Abstract

Using first-principles calculations in combination with the Eliashberg formalism, we systematically investigated phonon-mediated superconductivity in two-dimensional (2D) metal-boride crystals, consisting of a boron honeycomb network doped by diverse metal elements. Such 2D metal-boride compounds, named MBenes, are chemically exfoliable from single-crystalline layered ternary borides (MAB phases). First we identified the MBene layers with potential for superconductivity via isotropic Eliashberg calculations, considering a wide range of metal elements, with focus on alkaline earth and transition metals. Subsequently, we performed a detailed analysis of the prominent superconducting MBenes by solving the anisotropic Eliashberg equations. The obtained high critical temperatures (up to 72 K), as well as the rich multigap superconducting behavior, recommend these crystals for further use in multifunctional 2D heterostructures and superconducting device applications.

I. INTRODUCTION

The potential of two-dimensional (2D) materials in terms of future technological applications is well established [1–3], as demonstrated for example through both theoretical and experimental studies with regard to transistors [4, 5], energy harvesters [6–9], and sensors [10–12]. Recently, with the successful fabrication of 2D metallic materials such as In [13], Pb [14], NbSe₂ [15, 16], FeSe [17], MgB₂ [18], Mo₂C [19], Nb₂C [20], doped graphene [21–23], and twisted bilayer graphene [24], superconductivity has been added to the range of properties yielding possible applications. However, taking advantage of that potential requires a detailed investigation and understanding of the origins and behavior of the superconductivity in these two-dimensional systems, to ensure reproducibly robust superconducting behavior up to sufficiently high temperatures.

One of the well-known material families to examine the behavior of superconductivity at the 3D-to-2D transition are the layered hexagonal metal borides (MB₂) with *P6/mmm* space group symmetry. Among them, bulk MgB₂ has been extensively studied over the past two decades, and is still the electron-phonon (*e-ph*) mediated superconductor with highest

experimentally realized superconducting transition temperature at ambient pressure to date ($T_c = 39$ K) [25]. The experimental demonstration of two-gap superconductivity in this material has led to an immensely intensified interest in this area and a paradigm shift in superconductivity research. On that wave, superconductivity has also been experimentally validated in identical bulk crystals of ZrB_2 [26], NbB_2 [27], and TaB_2 [28]. When thinned down to monolayer thicknesses, MgB_2 was demonstrated to harbor a very strong influence of the surface states [29], leading to three-gap superconductivity with $T_c = 20$ K in the monolayer limit [30], strongly changing with every added monolayer, up to several nanometers thickness. Moreover, a strong increase in the T_c of 2D MgB_2 (to over 100 K) with hydrogenation and tensile strain have been revealed [31]. With the same crystal structure, single-layer AlB_2 has been predicted as a two-gap superconductor with $T_c = 26.5$ K [32, 33], surpassing single-layer MgB_2 , although its bulk form is not superconducting at all. Last but not least, one is also interested in possible growth of MB_4 two-dimensional crystals, with the metal layer sandwiched between two boron honeycomb networks. In that respect, Li, Be, Mg, Al, and Ga-based MB_4 structures have been recently predicted to possess a multigap superconducting nature, all with T_c above 30 K [33]. All together, the research to date clearly indicates the potential of layered metal boride systems to realize two-dimensional superconductivity.

It is therefore instructive to have a comparative analysis of different possible 2D metal-borides. When considering the experimentally grown bulk metal-borides with the same crystal symmetry [34], one notices that *e-ph* mediated superconducting properties of Ca, Sc, Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W and Re based 2D MBenes have not been explored. As a matter of fact, a recent first-principles study indicated the feasibility of synthesizing the layered MAB bulk crystals of hexagonal metal borides of Sc, Ti, Zr, Hf, V, Nb, Ta, Mo, and W, starting from the MAB bulk crystals [35], from which 2D MBenes are exfoliable (with name derived analogously to MXenes obtained from MAX bulk phases [36]). Note however that layer-by-layer exfoliation of these materials is not as straightforward as for graphene, due to the strong interaction between the metal and the boron layers. Therefore, one must consider several possible 2D formations, including MgB_4 (a metal layer sandwiched between two honeycomb B lattices, where the metal atoms are placed in the centers of honeycombs), MB_2 (a B layer in a honeycomb lattice and a layer of metal atoms sitting above the centers of honeycombs), and M_2B_2 (a B layer in a honeycomb lattice sandwiched between two layers

of metal atoms sitting above/below the centers of honeycombs). Therefore, in this paper we comprehensively investigated superconductivity in different exfoliable MBene structures, with particular attention to Ca, Sc, Ti, Zr, Hf, V, Nb, Ta, Cr, Mo, W, and Re based ones, in comparison to the previously studied Be, Mg, and Al based di- and tetra-borides. Following the selection of the most prominent superconducting MBenes, we detail their anisotropic superconducting properties, origin of their multiple superconducting gaps and their high critical temperature.

The organization of the paper is as follows. First, we describe the used computational approaches and adopted parameters for the calculations. Then, we present detailed isotropic Eliashberg theory results for all the considered materials. These results are then used to select the materials that potentially possess good superconducting properties. Finally, we summarize the results of detailed anisotropic Eliashberg calculations for the selected materials. Extensive additional results for electronic, vibrational, and superconducting properties are made available in the Supplementary Material.

II. COMPUTATIONAL METHODS AND DETAILS

The considered metal boride layers, 45 in total, were investigated through density functional theory (DFT), as implemented within the ABINIT [37, 38] code, using the Perdew-Burke-Ernzerhof (PBE) functional. Relativistic pseudopotentials from the PseudoDojo project [39] were used where we could include spin-orbit coupling (SOC) if necessary. Namely, we calculated electronic structures both without and with SOC for all compounds, and if significant differences were found in the states responsible for collective electron behavior, i.e. those near the Fermi level (E_F), we proceeded with the inclusion of SOC in further calculations. Within the used pseudopotentials $10 + N$ valence electrons were used for metal elements of group N , except for Be (4 valence electrons), and 3 valence electrons were taken into account for B. An energy cutoff value of 60 Ha for the plane-wave basis and a dense $36 \times 36 \times 1$ k -point grid were used to achieve high accuracy. The structures, with at least 16 Å of vacuum, were relaxed so forces on each atom were below 1 meV/Å. Subsequently, to calculate phonons and the electron–phonon coupling we employed density functional perturbation theory (DFPT), also within ABINIT [40], using the same electronic k -point grid and a $12 \times 12 \times 1$ phononic q -point grid. For the calculations of the supercon-

ducting state we used isotropic Eliashberg theory, a quantitatively accurate extension to the Bardeen–Cooper–Schrieffer (BCS) theory for phonon-mediated superconductivity [41–43]. We evaluated the superconducting T_c using the Allen–Dynes formula [44–46], and a screened Coulomb repulsion of $\mu^* = 0.13$ – a standard value for transition metal-based compounds [47]. In addition, the cohesive energy values of the structures (per atom) were calculated using the following formula:

$$E_{\text{coh}} = \frac{nE_M + lE_B - E_{M_nB_l}}{n + l}, \quad (1)$$

where E_M and E_B are the total energies of the isolated metal and B atoms, respectively, and $E_{M_nB_l}$ is the total energy of the corresponding 2D MBene. In view of this expression, materials with more positive E_{coh} indicate a higher chemical stability.

Subsequently, for the materials predicted to possess high T_c values, self-consistent solution of the fully anisotropic Migdal-Eliashberg equation was obtained through the Electron-Phonon Wannier (EPW) code [48–50]. For that part, first-principles calculations were performed with the Quantum ESPRESSO package [51], using the same PBE pseudopotentials. The cutoffs for the plane-wave basis and charge density were set to 100 Ry and 400 Ry, respectively. The k -point mesh for the integration in wave-vector space was set to $24 \times 24 \times 1$, and electronic smearing was performed within the Methfessel-Paxton scheme [52]. With these parameters, the structures were fully optimized until the Hellman-Feynman forces on each atom were below 10^{-4} Ry/bohr. The subsequent dynamical properties were calculated based on the density-functional perturbation theory as implemented in Quantum ESPRESSO package [53], using a q -mesh of $12 \times 12 \times 1$. The maximally localized Wannier functions [54, 55] required in the EPW calculations were interpolated by using an unshifted Brillouin-zone k -mesh of $12 \times 12 \times 1$. The solution of the anisotropic Migdal-Eliashberg equations was computed with interpolated k - and q -point grids of $240 \times 240 \times 1$ and $120 \times 120 \times 1$, which are sufficiently dense to guarantee convergence of the superconducting gaps. The cutoff for the fermion Matsubara frequencies $\omega_j = (2j + 1)\pi T$ was set to 0.5 eV and μ^* was the same as in the isotropic calculations (0.13).

III. RESULTS

As the first step, the equilibrium lattice structures of the considered three different metal-boride structures were predicted and compared with the available data. The calculated

in-plane lattice constants listed in the Supplementary Material are in good agreement both with available experimental values for bulk structures [18, 26, 34, 56] and with calculated values for the same single-layer crystals in the literature [29, 32, 57]. The phonon dispersions presented in the Supplementary Material clearly point out the dynamical stability of all the considered crystals except BeB_2 , TiB_4 , ZrB_4 , HfB_4 , and ReB_4 . Furthermore, the cohesive energy value, a widely accepted parameter used to evaluate the chemical stability of crystals (see Eq. 1), was evaluated for each monolayer. Promisingly, the corresponding values presented in Table II are comparable with the ones obtained for several experimentally realized monolayers, e.g., graphene (7.46 eV per atom), silicene (3.71 eV per atom), and black phosphorene (2.57 eV per atom). Based on these results, MB_4 is identified as the ground-state structure for Be, Mg, Ca, Sc, V, Cr, Mo, and Al based monolayers, while M_2B_2 was the favorable structure for the Ti, Zr, Hf, Nb, Ta, W, and Re based ones.

TABLE II. Calculated cohesive energy, E_{coh} , of the considered monolayer metal-boride structures.

Al	5.27	4.73	4.42				

Subsequently, we investigated the electronic properties of each material and we found nearly all the structures to be metallic. However, TiB_2 has a graphene-like band structure possessing a Dirac cone at the Fermi level as previously reported [57]. Also, BeB_2 , ZrB_2 , HfB_2 , CrB_4 , MoB_4 , and WB_4 were predicted to possess a very low electronic density of states at Fermi level due to single or multiple Dirac cones close to Fermi level, which is a clear obstacle for the formation of the superconducting state. As a result of this preliminary

analysis, we eliminated these materials and computed the superconducting properties for the other candidates. Our isotropic Eliashberg theory calculations show that five MB_4 , ten MB_2 , and two M_2B_2 crystals from Table I possess a sizable superconducting T_c . Among these materials, BeB_4 , MgB_4 , AlB_4 , AlB_2 , and MgB_2 have been previously investigated [32, 33]. Indeed, our results for the superconducting transition temperature T_c are comparable with the ones obtained in these references (where anisotropic Eliashberg theory was used). Also, the T_c obtained for MgB_4 in this study (22.2 K), is in very good agreement with the one calculated by Liao *et al.* in Ref. [58] (23.2 K).

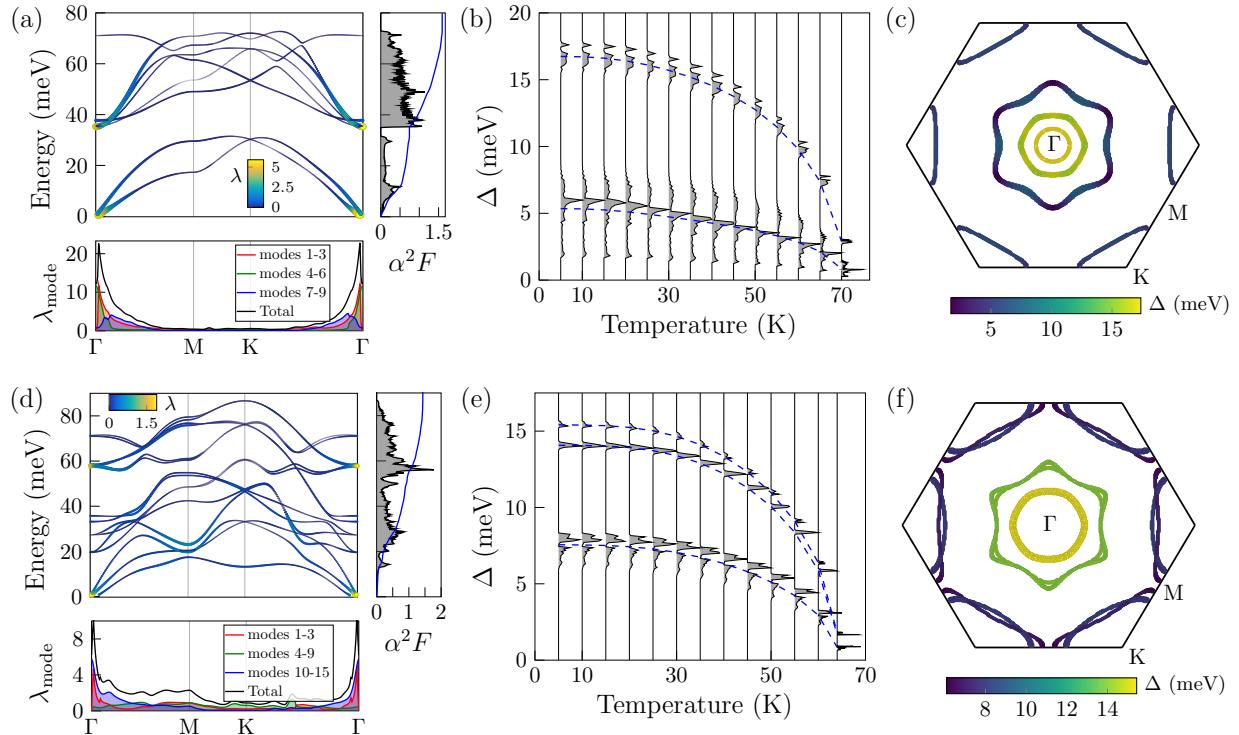

FIG. 1. Phonon dispersion with the mode-resolved electron-phonon coupling (EPC) indicated by colors and thickness, EPC λ_{mode} summed for three different groups of phonon modes, isotropic Eliashberg function $\alpha^2 F$, and EPC function λ for (a) CaB_2 and (d) CaB_4 . Evolution of the superconducting gap distribution for (b) CaB_2 and (e) CaB_4 . Momentum-dependent superconducting gap on the Fermi surface at 5 K for (c) CaB_2 and (f) CaB_4 .

Among these materials, CaB_4 , CaB_2 , NbB_2 , and ScB_2 with high T_c values 36.1, 41.6, 35.5, and 20.4 K were identified as the most prominent superconductors. Also, the group-5-based compounds VB_2 , NbB_2 , TaB_2 are worthy of further investigation. CaB_2 is similar to MgB_2

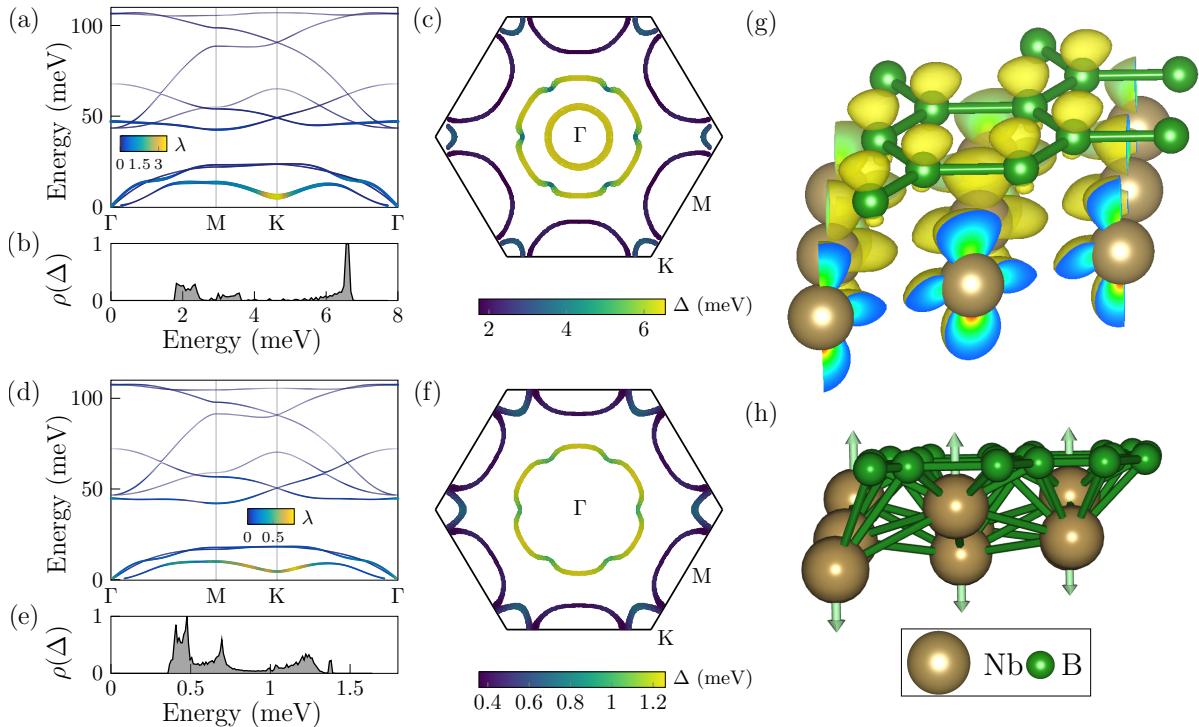

FIG. 2. Phonon dispersion with the mode-resolved electron-phonon coupling (EPC) indicated by colors and thickness for (a) NbB₂ and (d) TaB₂. Distribution of the superconducting gap of (b) NbB₂ at 5 K and (e) TaB₂ at 2 K. Momentum-dependent superconducting gap on the Fermi surface for (c) NbB₂ and at 5 K (f) TaB₂ at 2 K. (h) Vibrational mode corresponding to the softening in the lowest acoustic phonon modes of NbB₂ and TaB₂.

in terms of electronic properties, as one can see in Supplementary Material. Therefore, two distinct sets of partially occupied bands contribute to superconductivity, mainly arising from covalent bonding, σ ($s + p_{x,y}$) and non-bonding π (p_z), similar to MgB₂ [59]. In addition to the σ states around the Γ point, the non-bonding π orbitals, contributing Fermi level states centered around the K point, have distinct superconducting properties, as is also the case for MgB₂. As might be foreseen, the strong hybridization between B 2p and transition metal d states should be taken into consideration for VB₂, NbB₂, TaB₂, and ScB₂. Zhang *et al.* investigated how d orbitals stemming from Nb split into ($d_{xy}, d_x - d_y$), (d_{xz}, d_{yz}), and (d_{z^2}) around the Fermi level in NbB₂ [60].

Having evaluated the results obtained within the isotropic limit, we decided to focus

further on several materials with the most promising superconducting properties. Thus, we performed fully anisotropic Eliashberg calculations for CaB_2 , CaB_4 , VB_2 , NbB_2 , TaB_2 , and ScB_2 in order to fully characterize the origin and behavior of superconductivity in MBenes.

Calcium borides – CaB_2 and CaB_4 – have proven to be the most prominent superconductors among the considered structures. The Fermi surface of CaB_2 , shown in Fig. 1 (c), closely resembles that of MgB_2 and consists of two σ bands, a π band and a surface band. Both σ and π electronic states are localized in the layer of boron atoms while the surface state is mainly localized on top of the Ca layer facing vacuum. The Fermi surface of CaB_4 , shown in Fig. 1 (f), for the most part retains the same features as CaB_2 with one exception. Since the calcium layer in CaB_4 is fully encapsulated between two boron layers, this surface state is suppressed. The phonon band structures of the calcium borides, as shown in Fig. 1 (a) and (d), are quite different. In CaB_2 , acoustic and optical phonon modes are separated by an energy gap, which gets completely suppressed in CaB_4 , notwithstanding the similarity of the corresponding atomic displacements in both compounds. These different phonon dispersions lead to different electron-phonon coupling (EPC) in the two compounds, as shown in Fig. 1 (a) and (d). As can be seen from the Eliashberg function $\alpha^2 F$ of CaB_2 , acoustic and optical phonon modes contribute almost equally to the total EPC of 1.59, whereas for CaB_4 , due to the absence of the gap in the phonon dispersion, one cannot make a clear distinction in the Eliashberg function between acoustic and optical phonon modes. The total EPC of the calcium tetraboride is 1.43 which is slightly lower than in the diboride. As in the case of MgB_2 , in both calcium boride compounds, a significant part of the total EPC comes from one in-plane optical phonon mode, belonging to the E_2 class. λ_{mode} also reveals differences in the character of the EPC in CaB_2 and CaB_4 . Highly coupling phonon states in the former are fairly localized around the Γ point while in the latter there is also a sizable contribution from other parts of the Brillouin zone (particularly along Γ -M).

Based on our fully anisotropic Eliashberg calculations, we can analyze how different electronic states on the Fermi surface contribute to superconductivity, through the anisotropic gap spectrum $\Delta(\mathbf{k})$. At a temperature of 5 K, the largest Δ values, reaching as high as 17.4 meV in CaB_2 , stem from the B- σ states, while gaps of the B- π and surface states are highly anisotropic, ranging from 1.7 to 7.5 meV (Fig. 1 (c)). The superconducting gap distribution for calcium diboride, as shown in Fig. 1 (b), shows two distinct superconducting gaps: the strongest σ -state gap, and a highly anisotropic gap which is a hybrid formed by the π and

the surface electronic states. We proceeded solving the anisotropic Eliashberg equations for increasing temperatures until the gaps vanished, yielding a critical temperature of CaB_2 of around 70 K. The picture for CaB_4 is overall quite similar, with some notable differences. Since the surface electronic state is absent in the tetraboride, its lowest gap is now only formed by the π electronic state, and thus is much less anisotropic (Fig. 1 (e)). At 5 K temperature, the highest gap value of CaB_4 (15.6 meV) is less strong than in CaB_2 . Moreover, the two σ electronic sheets on the Fermi surface, which form the strongest gap in the diboride case, give rise to two slightly separated gaps in the tetraboride case (by less than 1 meV at 5 K). As compared to CaB_4 , the slightly weaker gap energies of CaB_4 result in a lower critical temperature of 64 K.

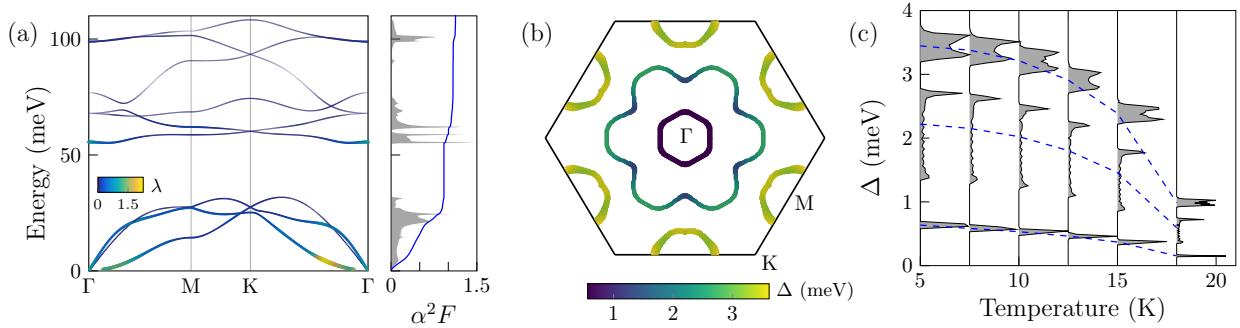

FIG. 3. Superconducting properties of VB_2 : (a) Phonon dispersion with the mode-resolved electron-phonon coupling (EPC) indicated by colors and size. (b) Momentum-dependent superconducting gap on the Fermi surface. (c) Evolution of the superconducting gap distribution with temperature.

Diborides of transition metals from group 5 of the periodic table – V, Nb and Ta – also show promise to be good superconductors. Particularly, the critical temperature of NbB_2 in the isotropic limit is 35.5 K, which is 3 times higher than the isotropic value in monolayer MgB_2 . However, for Nb and Ta diborides, we found that electronic smearing has a critical influence on phonons and EPC. With the standard electronic smearing value of 0.01 Ha, both structures show negative phonon frequencies in the vicinity of the K point, suggesting that the structures are not in their ground state. The unstable phonon mode, as shown in Fig. 2 (h), is an acoustic mode with out-of-plane vibrations of Nb/Ta atoms.

By increasing the smearing value to 0.03 Ha, we managed to get rid of the negative phonons (Fig. 2 (a) and (d)). However, the instability transforms into a softening in the

phonon dispersions of both compounds at the K point. These dips, as shown in Fig. 2 (a) and (d), form EPC hotspots with the values of the coupling much higher compared to all other phonon modes. Thus, the total EPC and the critical temperature of NbB_2 and TaB_2 strongly depend on the electronic smearing used in the calculation and so cannot be assessed precisely. It is nevertheless interesting that both compounds, despite being quite close in their electronic and vibrational properties, show quite disparate superconducting behavior. The superconducting gap structure is more complex in transition metal borides as compared to alkaline earth metal borides like MgB_2 and CaB_2 . For NbB_2 , this is mainly due to the outer semi-circular sheet around the Γ point, shown in Fig. 2 (c). The orbital character of this electronic sheet is not constant along the sheet because the character changes strongly at the points where the sheet shows indentations. Namely, everywhere on this Fermi sheet, except for the indentations, the electronic states mainly stem from the d_{z^2} orbital of Nb and p_z of B, which is similar to the states on the inner circular sheet around the Γ point (Fig. 2 (g)). These states from the two circular Fermi sheets form the strongest superconducting gap in NbB_2 (Fig. 2 (b)). All the remaining Fermi sheets together with the indent states of the outer sheet around Γ form the weakest, strongly anisotropic gap. Thus, in NbB_2 , electronic states from one Fermi sheet contribute to two distinct superconducting gaps. TaB_2 , calculated with the same parameters as NbB_2 , shows very weak EPC compared to the former, and all the Fermi sheets form a single anisotropic gap (Fig. 2 (e) and (f)).

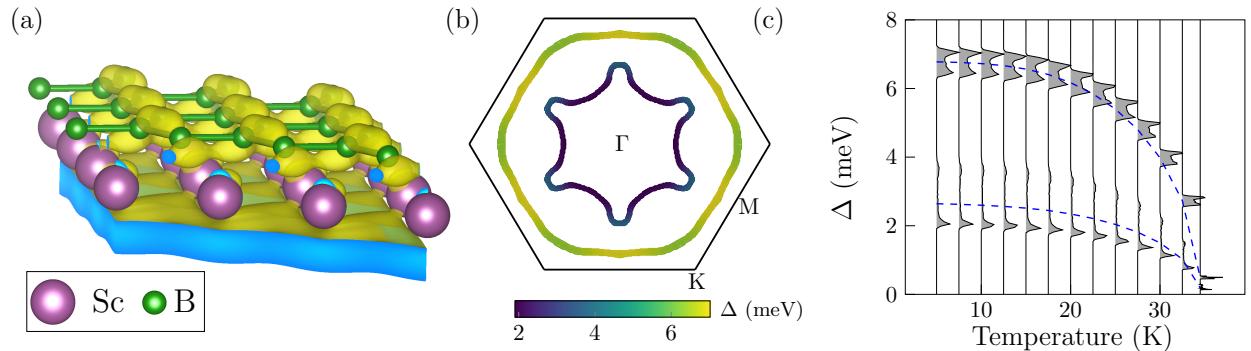

FIG. 4. (a) Surface electronic state of ScB_2 , corresponding to the inner sheet of the Fermi surface. Superconducting properties of ScB_2 , namely (b) momentum-dependent superconducting gap on the Fermi surface, and (c) evolution of the superconducting gap distribution with temperature.

The lightest transition metal of group 5, vanadium, forms a diboride structure without unstable phonons, even when calculated with the electronic smearing as low as 0.01 Ha

(Fig. 3 (a)). Considering the out-of-plane nature of the unstable mode in both NbB_2 and TaB_2 (Fig. 2 (h)), it appears that V, being lighter than its group neighbors, does not cause rippling of the structure, rendering it dynamically stable. Even though V, Nb and Ta belong to the same group, the Fermi surface of VB_2 (Fig. 3 (b)) is quite different as compared to the diborides of Nb and Ta. In VB_2 , there is no sheet around the K point and the two sheets around the Γ point have a hexagonal and a flower-like shape respectively, in contrast to almost completely circular sheets in the two other diborides. The hexagonal sheet stems from a combination of out-of-plane d orbitals with considerable contribution of the d_{z^2} orbital, whereas the flower-shaped sheet is a mixture of in-plane and out-of-plane d orbitals of V without d_{z^2} contribution. VB_2 does share a common sheet with other diborides, namely the circular sheet around the M point which corresponds to out-of-plane d orbitals of the M atom (d_{xz} and d_{yz}).

The total electron-phonon coupling for VB_2 is 1.13 with the main contributions coming from the acoustic phonon modes as well as the lowest optical mode representing out-of-plane vibrations of boron atoms, as shown in Fig. 3 (a). Interestingly, the superconducting gap on the Fermi surface shows the opposite pattern for VB_2 as compared to other MBenes of group 5. The electronic sheets around the Γ point, which are attributed mainly to d_{z^2} orbital of the M atom, represent the strongest gap in both NbB_2 and TaB_2 (Fig. 2 (c) and (f)) while in VB_2 this state gives rise to the weakest gap. This is true for the circular state around the M point. Unlike in the case of Nb and Ta, VB_2 has an additional intermediate gap stemming from the flower-shaped Fermi sheet around the Γ point. Thus, VB_2 is a three-gap superconductor. Our calculations show that the gaps vanish at the critical temperature of around 18.5 K.

The last material we have considered in more detail was ScB_2 . Scandium belongs to group 3 of the periodic table, on the border between alkaline earth metals and transition metals. Since Sc has only one d electron in its outer shell, other electronic states can contribute more to the electronic states around the Fermi level. Therefore, ScB_2 represents an intermediate case between CaB_2 and the MBenes based on group 5 transition metals. The Fermi surface of ScB_2 , shown in Fig. 4 (b), consists of two sheets. The inner sheet corresponds to a surface state (Fig. 4 (a)), akin to the one found in alkaline earth metal MBenes such as MgB_2 and CaB_2 . However, in alkaline earth MBenes the surface state stems from Mg/Ca- p states, whereas in ScB_2 it mainly has Sc-s character, because of scandium's

different electronic configuration. The states of the outer sheet are a mixture of the boron p_z orbital and in-plane d orbitals of Sc. The total isotropic EPC of ScB_2 amounts to 1.27. Anisotropic Eliashberg calculation show that ScB_2 is a two-gap superconductor (Fig. 4 (b)), with the strongest gap stemming from the outer Fermi sheet and the weakest gap stemming from the inner sheet. The resulting critical temperature is rather high – around 34.5 K.

IV. CONCLUSION

Our systematic investigation performed with both isotropic and anisotropic Eliashberg theory calculations broadly sheds light on the potential of two-dimensional metal boride systems as superconducting materials. High critical temperatures (up to 72 K), as well as multigap superconducting behavior in CaB_2 , CaB_4 , VB_2 , NbB_2 , TaB_2 , and ScB_2 structures were shown and detailed in this work. Coupled with the advent of their fabrication [61, 62], here shown different electronic structures and Fermi surface configurations together with the demonstrated richness of the superconducting behavior in 2D metal-borides recommend their versatility for further exploration in fundamental (multi)functional heterostructures as well as potential device applications.
